Increasing prevalence of childhood obesity poses threats to the global health burden. Because this rising prevalence cannot be fully explained by traditional risk factors such as unhealthy diet and physical inactivity, early-life exposure to endocrine disrupting chemicals (EDCs) is recognized as emerging novel risk factors for childhood obesity. EDCs can disrupt the hormone-mediated metabolic pathways, affect children's growth and mediate the development of childhood obesity. Many organic pollutants are recently classified to be EDCs. In this review, we summarized the epidemiological and laboratory evidence related to EDCs and childhood obesity, and discussed the possible mechanisms underpinning childhood obesity and early-life exposure to non-persistent organic pollutants (phthalates, bisphenol A, triclosan) and persistent organic pollutants (dichlorodiphenyltrichloroethane, polychlorinated biphenyls, polybrominated diphenyl ethers, per- and polyfluoroalkyl substances). Understanding the relationship between EDCs and childhood obesity helps to raise public awareness and formulate public health policy to protect the youth from exposure to the harmful effects of EDCs.

Keywords: Endocrine disrupting chemicals, Childhood obesity, Persistent organic pollutants, Early-life exposure

Introduction

Childhood obesity is increasingly recognized as an important health hazard. In addition to the social stigma and psychological consequences, obesity is associated with increased risk of type 2 diabetes mellitus, hypertension, hyperlipidemia, sleep apnea, cardiovascular disease, cancer and arthritis.1-3 There is also growing evidence showing that childhood obesity may herald adult obesity.4-6 The Global Burden of Diseases study recently estimated that nearly 110 million children and adolescents were obese.7 Alarmingly, the prevalence of youth that are overweight and obesity has doubled in the last three decades, with its rate of increase greater than that of adult obesity in most countries.7

Unhealthy diet and physical inactivity are traditional risk factors for obesity. Greater energy intake than energy expenditure results in positive energy balance and obesity.8 However, lifestyle and genetic factors are unable to fully explain the rising prevalence and incidence of overweight or obese children.9,10 Growing evidence from epidemiological studies indicates that exposure to environmental chemical pollutants may contribute to this global epidemic of childhood obesity.11-13 Children who have early exposure to these pollutants even during intrauterine period may experience either an increase in body weight at young age or a catch-up increase of body weight in later life.14,15

Endocrine disrupting chemicals

Endocrine disrupting chemicals (EDCs) are a class of environmental pollutants that affect...
the endocrine function and modulate our risk of developing metabolic diseases including obesity. EDCs include organic chemicals (such as nonpersistent organic chemicals and persistent organic pollutants [POPs]) and its analogs (such as alkylphenols). They are mainly man-made chemicals or compounds which are widely found in food, daily use products/materials, and the environment (such as water, indoor air, and dust), that can accumulate in human body through the food chain. Intraplacentual transfer, breast milk consumption and children’s hand to mouth behavior are the common ways that infancy and young children are exposed to EDCs in early-life. Table 1 summarizes the characteristics of some EDCs.

Emerging epidemiological and biological evidence suggests that rapid weight gain during infancy or later childhood might be related to maternal or early-life exposure to EDCs. In this review, we discuss this interesting relationship and the potential mechanisms.

1. Nonpersistent organic chemicals

Nonpersistent organic chemicals have a short half-life in the range of less than 24 hours to one week and include phthalates, bisphenol A and triclosan.

Phthalates

Phthalates (phthalate esters) are a family of esters of phthalic acid and are mainly used as plasticizers to soften polyvinyl chloride or increase the durability and longevity of consumer products (such as containers and plastics) (Table 1). Phthalates can be found in food, pharmaceutical, cosmetic and baby caring products. Ingestion, respiration or dermal absorption are the routes for phthalates exposure. Compared to high molecular weight (HMW) congeners (such as DEHP [di-2-ethylhexyl phthalate], DnOP [di-n-octyl phthalate]), low molecular weight (LMW) phthalates (such as DEP [diethyl phthalate], DnBP [di-n-butyl phthalate], and DiBP [di-isoo-butyl phthalate]) have higher bioaccumulation factors, which may lead to high concentration within the body and increase the health risk. In many developed countries, LMW phthalates have been gradually replaced by HMW phthalates or nonphthalates plasticizers for health concerns. However, LMW phthalates (such as DEP, a common solvent for fragrance) are still frequently detected in consumer products.

Urinary or serum phthalates and their metabolites have been found to be significantly associated with body size and body mass index (BMI) in children and adolescents based on epidemiology studies (Table 2). A 4-year prospective study involving 1,239 girls in the United States (US) showed that early exposure to high concentration of LMW phthalates (MEP [monoethyl], MBP [mono-n-butyl], MbiBP [mono-isobutyl]) at age 6–8 years were positively associated with weight gain (β=1.2, 95% confidence interval [CI], 0.41–2.1 kg/m²) and increased waist circumference (β=3.9, 95% CI, 1.3–6.5 cm) than later exposure at age 7–13 years. Furthermore, MEHP (mono-(2-ethylhexyl) phthalate), the urinary metabolites of DEHP, were positively correlated with fasting glucose to insulin ratio (FGR) (Spearman’s correlation coefficient, 0.341; P=0.039). DEHP exposure in female mice was associated with increased abdominal visceral fat accumulation in the offspring. However, another Spanish birth cohort study reported that high maternal urine HMW phthalates (including MBzP [mono-benzyl phthalate], MEHP, MEHHP [mono(2-ethyl-5-hydroxyhexyl) phthalate], MEOHP [mono(2-ethyl-5-oxohexyl) phthalate], and MECPP [mono(2-ethyl-5-carboxypentyl) phthalate]) was negatively associated with body weight z-score in infants aged 0–6 months (β=-0.41, 95% CI, -0.75 to -0.06). Therefore, more studies are needed to delineate the potential effects of phthalates on childhood obesity taking sex into consideration.

BPA, bisphenol A; DDT, dichlorodiphenyltrichloroethane; PCB, polychlorinated biphenyl; PBDE, polybrominated diphenyl ether; PFAS, Per- and polyfluoroalkyl substance.
Bisphenol A

Bisphenol A (BPA) belongs to bisphenols, a group of chemical compounds with 2 hydroxyphenyl functionalities. BPA is commonly used in consumer plastics and polycarbonate products (such as water bottles, plastic food containers, and cans), as well as medical materials (such as dental fillings) (Table 1). Oral absorption is the major exposure pathway because BPA can leak into food and beverage from containers.\(^{41-43}\) Its short biological half-life (about 6 hours) allows for easy detection of BPA and its conjugates in urine.\(^{44}\)

Table 2 summarizes the cross-sectional and prospective cohort studies that have examined the relationship between exposure to BPA and risk of childhood obesity. In the Columbia Center for Children’s Environmental Health birth cohort study, increased exposure to BPA in children aged 7 years was associated with high fat mass index, body fat and waist circumference\(^{45}\) (Table 2). Maternal BPA concentration was shown to be associated with increased plasma leptin levels in boys.\(^{46}\) Some cross-sectional studies has found that early-life exposure to BPA is positively associated with obesity in children and adolescents (Table 2).\(^{47,48}\)

In rats, perinatal exposure to BPA promotes adipogenesis and weight gain.\(^{49,50}\) Results from a mouse study also revealed that exposure to BPA during fetal period led to age-related increase in body weight due to an increase in adipose tissue mass and volume.\(^{23}\)

Several BPA substituents such as bisphenol F (BPF) and bisphenol S (BPS) are currently available. However, these substituents have a wide spectrum of toxicities with potential endocrine-disrupting effects, particularly BPS which has been shown to be as hormonally active as BPA.\(^{52,53}\) However, a study of 1,521 participants aged 20 years or older in the US reported that only urinary BPA was significantly associated with obesity, but not BPF or BPS.\(^{54}\) Continued biomonitoring of bisphenols and evaluation of their health effects in human are warranted.

Triclosan

Triclosan (2,4,4’-trichloro-2’-hydroxy-diphenyl ether) is an antibacterial reagent commonly found in pharmaceuticals

</tbody>
</table>
and personal care products such as toothpastes, cosmetics, soaps, surgical cleaning treatment reagents and toys (Table 1). Similar to BPA, its biological half-life is very short (<24 hours), and the majority (24%–83%) was excreted in urine after 4 days exposure. An individual can also be exposed to triclosan via skin contact.

Recent studies have suggested triclosan may be toxic to humans in addition to having antibacterial activity. Pregnant rats exposed to triclosan from 8 days before mating to lactation day 21 developed primary hypothyroidism with decreased total serum T4 and T3 level. Pups also had a lower body weight on postnatal day 20 than that were not exposed to triclosan. Although intrauterine exposure to triclosan was associated with reduced body weight in offspring, male triclosan-exposed rats were 12.5% heavier at 4 months (β=0.4, 95% CI, 0.2–1.1) and females were 19% heavier for at 8 months (β=0.4, 95% CI, 0.2–1.1). Taken together, these data indicate an inconsistent relationship between triclosan exposure and childhood obesity, perhaps due to variations in study design and/or participants’ characteristics.

1. Persistent organic pollutants

POPs are EDCs that persist in the environment and tend to bioaccumulate through food chain. Due to their lipophilicity, most POPs can accumulate in adipose tissue, which then act as a toxicity pool.
organochlorine pesticides group and refers to a mixture of 1,1,1-trichloro-2,2-bis(p-chlorophenyl)-ethane (p,p'-DDT) and 1,1,1-trichloro-2-(p-chlorophenyl)-2-(o-chlorophenyl)-ethane (o,p'-DDT). Although the usage of DDT has been banned worldwide since the last century, it is still commonly used in malaria-endemic countries such as sub-Saharan Africa and India. Of note, its half-life in the atmosphere and soil can be as long as 2.5 years and 20–30 years, respectively (Table 1). Previous studies revealed that DDT posed negative effects on the reproductive system by altering endometrial function through kinase transduction pathway via an estrogen receptor-independent mechanism. DDT could increase the gene expressions regulating adipogenesis such as peroxisome-proliferator activated receptor-γ (PPARγ) and CCAAT/enhancer-binding protein α (C/EBPα), enhance adipocyte differentiation from preadipocytes and adipogenic stem cells, which resulted in increased cellular uptake of fatty acids.

Several studies have demonstrated that prenatal exposure to DDT and dichlorodiphenylchloroethene (DDE) is associated with childhood obesity, with possible gender differences. Every 10-fold increase in prenatal DDT and DDE concentrations was positively associated with increased odds of becoming overweight or obesity in boys (for o,p'-DDT, adjusted odds ratio [aOR], 2.5; 95% CI, 1.0–6.3; for p,p'-DDT, aOR, 2.1; 95% CI, 1.0–4.5), but not reported in girls. This obesogenic effect was evident in the first 6 months after birth and might persist until adolescence. However, isomers of DDT may have different effects. Every unit increase in p,p'-DDT was associated with increased birth weight (β=274 g; 95% CI, 1.0–4.5), while exposure to either o,p'-DDT was associated with decreased birth weight (β=-153 g; 95% CI, -296 to -10). Given the similarity in molecular structure between DDT and thyroid hormones, it has been postulated that DDT may promote obesity via disruption of thyroid homeostasis, which resulted in increased cellular uptake of fatty acids. Therefore, more epidemiological studies are needed to clarify the obesogenic effects of different congeners and total effects of PCBs mixture.

### Polychlorinated biphenyls

Polychlorinated biphenyls (PCBs) are derived from biphenyl, where the hydrogen atoms of biphenyl are replaced by chlorine atoms to form 209 different congeners. PCBs are widely employed in industrial production (transformers and large capacitors), nominally closed systems (hydraulic fluids and lubricants) and open applications (carbonless copy paper) (Table 1). Use of PCBs has been banned since 2004. However, they continue to enter the environment from consumer products and waste. Similar to PCBs, replacement of hydrogen atoms by bromine atoms in biphenyl ethers generates 209 congeners of PBDEs. In general, the biological half-life of PBDEs is long, which ranges from 1.8–3 years for BDE-47 to 6.6–11.7 years for BDE-153. Infants (73±7 ng/g lipid) and young children (28±8 ng/g lipid) had higher concentration of total PBDEs than adults (15±5 ng/g lipid) after exposure via maternal transfer and breast milk consumption. BDE-47, -99, -100, and -153 were the most abundantly detected congeners. In a US longitudinal birth cohort involving 224 mother-child pairs, every 10-fold increase in maternal serum PBDEs (including BDE-47, -99, -100, -153) had an inverse association with BMI z-scores in girls (β=-0.41; 95% CI, -0.87 to -0.05) (Table 2). A cohort study involving 413 mothers in Sweden demonstrated that PBDEs (sum of BDE-47, -99, -100, and -153) level in breast milk was associated with birth weight in the multivariate model (β=-106; 95% CI, -158 to -54). Another cohort study involving 318 mother-child pairs reported no statistically significant associations observed between prenatal PBDEs (including BDEs-28, -47, -99, -100, -153) and birth weight z-score, whereby a 10-fold increase in maternal serum BDE-153 was associated with a lower BMI z-score at 2–8 years, decreased waist circumference at 4–8 years, and decreased body fat percentage at 8 years (Table 2). Our research group and others have demonstrated that PBDEs induced in vitro adipocytes differentiation by increasing the expressions of genes involved in the adipogenesis and lipid accumulation. In mice models, prenatal exposure of BDE 47 worsened hepatic steatosis and metabolic profiles in the offspring, possibly via the alteration of gut microbiome and impairment of insulin sensitivity. In male rats, a low dose of BDE 47 increased plasma insulin-like growth factor...
1 level and impaired glucose metabolism. These results suggest that BDE 47 can be an environmental obesogen, while the obesogenic effects of other PBDEs congeners remain to be verified in epidemiological and laboratory studies.

**Per- and polyfluoroalkyl substances**

Per- and polyfluoroalkyl substances (PFAS) belong to a class of synthetic fluorinated chemicals that are widely employed as stain- or oil-resistant coating materials for textiles, carpet, food containers and industrial surfactants. The biological half-life of PFAS is more than 4 years. Given their relatively stable structure, PFAS are extremely resistant to chemical and biological degradation, with high bioaccumulation in human body through the food chain. Four types of PFAS including perfluorooctanoic acid (PFOA), perfluorooctane sulfonic acid (PFOS), perfluorononanoic acid (PFNA), and perfluorohexane sulfonic acid (PFHxS), are the most universally detected in the serum of pregnant women and children as well as in general population.

Compared to health-based guidance of 0.04 µg/L for PFOA in drinking water, PFOA and PFOS are the most frequently detected congener in the PFAS family and their geometric mean concentrations in pregnant women are 5.80 and 2.32 ng/mL respectively, while the mean concentration of PFNA and PFHxS are 0.66 and 0.61 ng/mL. Excess maternal PFOA exposure was associate with increased waist circumference (β=4.3; 95% CI, 1.7–6.9) in children at 8 years old. Furthermore, high prenatal PFAS, PFOA and PFOS levels were associated with increased serum total cholesterol, low-density lipoprotein cholesterol, and triglyceride levels in children.

Interestingly, another prospective cohort study involving 665 mother-child pairs observed inverse associations between PFOS or PFOA and homeostatic model assessment of insulin resistance when children were around 7 years old (β=-10.1, 95% CI, -16.4 to -3.3; and β=-0.1, 95% CI, -17.3 to -2.3 for PFOS and PFOA, respectively).

In animal models, PFOA, PFOS and perfluoroalkyl acids increase lipid accumulation, promote insulin resistance and induce adipocytes differentiation, resulting in obesity. However, in utero exposure to C57BL/6J-Min/+ (multiple intestinal neoplasia) mice with either PFOS or PFOA did not significantly increase the body weight of offspring. Therefore, the obesogenic effects of PFOA and PFOS need to be verified with additional animal studies and epidemiological data.

**Possible mechanisms linking POPs, obesity, and diabetes**

There are several postulated mechanisms that can explain the effects of EDCs on early-life obesity, including mitochondrial dysfunction and epigenetic regulation.

**Mitochondrial dysfunction and oxidative stress**

Mitochondrial dysfunction can induce the development of cardiometabolic diseases including obesity, diabetes and cancer. Mitochondrial dysfunction increases the accumulation of diacylglycerol (metabolites of fatty acids metabolism) and reactive oxygen species (ROS), particularly in insulin-resistant tissues (such as liver tissue).

In obese mice, exposure to a PCB mixture (Aroclor 1260) impaired mitochondrial function and increased adipokines level, which could mediate inflammation and insulin resistance. A study in C57BL/6J mice demonstrated that visceral obesity, insulin resistance and glucose intolerance occurred when mice were fed salmon contaminated with PCBs (PCB-28, -52, -101, -138, -153, -180). Taken together, these findings suggest that mitochondrial dysfunction is one of the key factors in the development of obesity associated with chronic exposure to POPs.

Oxidative stress also contributes to the development of obesity. Multiple studies showed that ROS such as H$_2$O$_2$ can induce adipocyte differentiation and lipid peroxidation, leading to obesity and metabolic syndrome. In addition to mitochondrial dysfunction, ROS increases the transcriptional activity of PPARy and C/EBPα, which are the key transcriptional factors for adipogenesis. Oxidation stress is often correlated with DNA oxidation because obesity causes significant oxidative stress, oxidative DNA damage, and changes of DNA methylation pattern in the tissue. BDE-47 has been reported to increase the intracellular and mitochondrial ROS levels, adipocyte differentiation, lipid peroxidation, and DNA oxidation. Importantly, inhibition of mitochondrial ROS production suppressed BDE-47-induced lipid accumulation and insulin resistance. These results were confirmed by a decreased ratio of GSH to GSGG, which are biomarker of oxidative stress.

**DNA methylation**

DNA methylation, an epigenetic mechanism, involves addition of methyl groups to DNA, thereby modifying the activity of the DNA segment without changing the sequence. This can repress gene transcription, especially when methylation sites are located in a promotor region. Many POPs and BPA can induce DNA methylation. Among 70 general workers in Arctic Council (which monitored the levels of pollutants in all Arctic environment), high serum POPs levels were associated with global DNA hypomethylation. An inverse relationship was found between plasma levels of methylation of cytosine residues and many POPs including p,p’-DDT.

In a mouse model with the 3T3-L1 cell line, exposure to BDE-47 and PCB-153 altered DNA methylation levels. Three hypomethylation CpG sites were located in the promoter region of PPAR γ2, which is the key transcription...
factor for adipogenesis. In vitro studies had demonstrated that PFOS and PFOA induced adipocyte differentiation via DNA methylation and Nrf2 pathways. Thus, DNA methylation may be one of the mechanisms by which organic pollutants predispose animals to obesity.

Conclusions

This is epidemiological and preclinical evidence that perinatal exposure to EDCs has detrimental effects in children. Early-life exposure to EDCs may impose an increased risk of obesity in later life, likely via impaired mitochondrial function and epigenetic dysregulation. Well-designed animal and prospective cohort studies are needed to provide more mechanistic insights on the relationships between EDCs and childhood obesity. Heightened efforts from governments and other stakeholders are warranted to formulate effective health policy and disseminate health education programs to raise public awareness to protect our youth from the detrimental effects of EDCs.
